Systemic inflammation in humans may be triggered by infection, termed sepsis, or non-infective processes, termed non-infective systemic inflammatory response syndrome (SIRS). MicroRNAs regulate cellular processes including inflammation and may be detected in blood. We aimed to establish definitive proof-of-principle that circulating microRNAs are differentially affected during sepsis and non-infective SIRS. Critically ill patients with severe ($n = 21$) or non-severe ($n = 8$) intra-abdominal sepsis; severe ($n = 23$) or non-severe ($n = 21$) non-infective SIRS; or no SIRS ($n = 16$) were studied. Next-generation sequencing and qRT-PCR were used to measure plasma microRNAs. Detectable blood miRNAs ($n = 116$) were generally up-regulated in SIRS compared to no-SIRS patients. Levels of these 'circulating inflammation-related microRNAs' (CIR-miRNAs) were 2.64 (IQR: 2.10–3.29) and 1.52 (IQR: 1.15–1.92) fold higher for non-infective SIRS and sepsis respectively ($p < 0.0001$), hence CIR-miRNAs appeared less abundant in sepsis than in SIRS. Six CIR-miRNAs (miR-30d-5p, miR-30a-5p, miR-192-5p, miR-26a-5p, miR-23a-5p, miR-191-5p) provided good-to-excellent discrimination of severe sepsis from severe SIRS (0.742–0.917 AUC of ROC curves). CIR-miRNA levels inversely correlated with pro-inflammatory cytokines (IL-1, IL-6 and others). Thus, among critically ill patients, sepsis and non-infective SIRS are associated with substantial, differential changes in CIR-miRNAs. CIR-miRNAs may be regulators of inflammation and warrant thorough evaluation as diagnostic and therapeutic targets.

Sepsis is defined as a systemic inflammatory response syndrome (SIRS) driven by infection¹. Severe sepsis (sepsis accompanied by acute organ dysfunction) is a leading cause of death worldwide and the most common cause of death among patients on Intensive Care Units (ICUs)². Critically ill patients may also develop SIRS driven by non-infective processes such as tissue ischemia. Sepsis and non-infective SIRS are hard to differentiate clinically but have very different therapeutic implications.

Understanding the immunopathology of sepsis and non-infective SIRS is vital for the development of novel diagnostics and treatments and for the appropriate use of antibiotics and novel immunotherapies. Much is known about the inflammatory responses which underlie sepsis and biomarkers of inflammation have been identified³. However there is growing recognition of the importance of anti-inflammatory, regulatory processes which accompany SIRS and sepsis⁴. These are physiological in that they terminate inflammation during recovery, and may be pathological causing sepsis-related immunosuppression. Ultimately, understanding how SIRS and sepsis are regulated may be key to developing novel biomarkers and interventions⁵.

MicroRNAs (miRNAs) are small (~22 nt) regulatory RNAs that function as post-transcriptional gene regulators^{6,7}. Out of the 2588 described human miRNAs (miRBase.org), approximately 200 miRNAs have been reported circulating in the human blood in health and disease^{8–10}. The impact of disease on circulating miRNAs has been assessed principally in the context of cancer^{11–13}. A handful of studies have measured miRNAs present in the blood of sepsis patients, and reported conflicting findings^{14–21}. Other studies have assessed specific candidate miRNAs based on leukocyte inflammatory responses in experimental models^{22–26}. Advances in

Group Name	n	Age (years)	SOFA scores	Surgical: Medical ratio	Time to sample (hours)	CRP (ng/ml)	PCT (ng/ml)	F:M ratio (♀:♂)	[Hb] mg/L plasma
Severe SIRS	23	58.5 ± 17.0	7.56 ± 2.31	6:17	0.73 (IQR: 0.22–2.3)	19.8 ± 32.7	1.73 ± 3.85	12:11 (52.2%)	155 ± 110
Severe Sepsis	21	67.7 ± 12.9	8.19 ± 2.68	21:0	0.88 (IQR: 0.33–2.5)	156 ± 76.9	21.9 ± 28.7	13:8 (61.9%)	215 ± 145
Non-severe SIRS	21	61.0 ± 14.0	1.29 ± 0.96	18:3	0.67 (IQR: 0.41–2.8)	20.6 ± 34.3	0.29 ± 0.34	12:9 (57.1%)	216 ± 159
Non-severe Sepsis	8	58.1 ± 23.3	1.13 ± 0.99	8:0	1.6 (IQR: 0.40–4.2)	159 ± 69.5	5.77 ± 9.66	3:5 (37.5%)	115 ± 96.3
NO SIRS	16	64.9 ± 14.6	4.19 ± 3.41	15:1	0.70 (IQR: 0.14–2.4)	19.2 ± 20.3	0.77 ± 1.00	11:5 (68.7%)	160 ± 133

Table 1. Demographics, severity of illness and key inflammatory biomarkers of the patients used in the study.

array and sequencing technologies now allow genome-wide screening for miRNAs, directly in human serum and plasma^{27,28}, but studies which have taken this approach have been hampered by lack of robust normalization to properly quantify miRNA levels, small sample sizes and heterogeneous patient populations^{14,17}.

In this study, we set out to establish definitive proof-of-principle that circulating microRNAs are differentially affected during systemic inflammation in critically ill patients depending on etiology. We studied a cohort of patients robustly characterized at the time of admission to critical care²⁹ and selected tightly defined groups of patients with sepsis, non-infective SIRS, and critical illness without SIRS (no-SIRS patients). We used next-generation sequencing (NGS³⁰) to identify normalizer miRNAs (present at consistent levels between patient groups) and to establish a long-list of candidate miRNAs differentially present in the blood of patients with sepsis, non-infective SIRS and without SIRS. We then used miRNA qRT-PCR to validate the most differentiating miRNAs and explore their performance in distinguishing sepsis from non-infective SIRS used singly and in combination.

We find that there is a general increase in the levels circulating miRNAs in the blood of patients with sepsis or non-infective SIRS compared with controls, and that this is more marked for non-infective SIRS than sepsis patients. We term these circulating inflammation-related miRNAs (CIR-miRNAs). Furthermore we find that the levels of CIR-miRNAs are differentially affected in sepsis and non-infective SIRS. Of note, among sepsis and SIRS patients, the blood levels of CIR-miRNAs inversely correlate with the plasma levels of key pro-inflammatory mediators such as interleukin-(IL)-1, IL-6, IL-8 and C-reactive protein (CRP), previously identified in systemic inflammation and sepsis^{3,29}. CIR-miRNAs may be anti-inflammatory regulators of inflammation in patients with sepsis or non-infective SIRS and further investigation of their function and potential as disease markers and therapeutic targets is warranted.

Materials and Methods

Study Population. Patients comprised unselected adult admissions to a mixed medical/surgical intensive/high-dependency care unit (ICU/HDU) at an English acute hospital (Brighton and Sussex University Hospitals NHS Trust). For each patient, we gathered data describing demographics, reason for admission to ICU/HDU (i.e., medical/surgical patient), severity of illness (Sequential Organ Failure Assessment (SOFA) score in the first 24 hours), comorbidities, focus of infection, and routine clinical blood test results. Patients were categorized as having sepsis, non-infective SIRS or no-SIRS using standard criteria²⁹. To minimize heterogeneity within groups, we included only patients with abdominal sepsis (defined as surgically or radiologically identified focus of infection within the abdomen) and defined distinct levels of severity: severe (SOFA ≥ 6) and non-severe (SOFA ≤ 3) sepsis/SIRS; patients with intermediate SOFA scores of 4–5 were excluded, defining 5 experimental groups (Table 1). Study blood samples were collected within a median time of 0.78 (IQR: 0.30–2.5; n = 89) hours of ICU admission with a maximum collection time of 5.8 hours. There was no statistical difference (p = 0.740, ANOVA) in time of sample collection between the groups (Table 1).

Ethics Statement. Written informed consent or consultee approval to enroll was secured for all study participants. Under the UK Law (Mental Capacity Act) a consultee is someone (usually a next of kin, friend or family member) who gives approval for a patient who lacks capacity to be enrolled to a study, thus allowing such patients to participate in studies addressing the illness which affects them. This study was approved by the North Wales Research Ethics Committee (Central and East, reference 10/WNo03/19) and carried out in accordance with the approved guidelines. All data were anonymized.

Preparation of NGS samples from plasma. Red blood cell (RBC) lysis can bias microRNA content in plasma^{31,32}. The concentration of free hemoglobin ([Hb]) was measured in patient plasma by the Harboe spectrophotometric method^{33,34} and hemolytic³⁵ samples with [Hb] > 0.6 g/L³⁶ were excluded. Plasma pools were formed by combining equal volumes of patients' plasma (Table 1). Total RNA was then extracted using the miRVana™ PARIS™ kit (Life Technologies)¹³. On average, we recovered 679 ± 165 pg RNA/μl plasma (mean ± SD); of this 849 ± 206 ng (mean ± SD) RNA (stored at −80 °C) were used for NGS technical duplicates. NGS cDNA libraries were prepared and validated at ARK Genomics (University of Edinburgh, UK) using specific barcodes for each cDNA library (Illumina TruSeq Small RNA sample) following manufacturer instructions.

Figure 1. Patients plasma tested for miRNAs in Illumina NGS. Plasma total RNA was extracted from 10 pools (representative of 89 ICU patients, as in Table 1) using the miRvana PARIS technology and then human miRNAs were sequenced using the Illumina next generation sequencing (NGS) platform. (A) Representative plots show the number of blood miRNAs (x-axis, sorted based on their abundance in the first duplicate of SIRS) and relative NGS counts (y-axis), in SIRS, sepsis and no-SIRS patients. Many miRNA were expressed below $1/10^5$ NGS counts (orange shadowed areas) consistently across all pools and were excluded from further analysis. (B) Prolife of miRNA distribution after miRNAs with $<1/10^5$ counts (orange areas) in all pools were excluded. (C) miRNA counts in 2 identical replicates are shown in scatter plots for SIRS, sepsis and no-SIRS patients. Reproducible results were obtained for miRNAs with NGS counts $>10/10^5$ (red lines) and miRNA in the grey area were excluded. (D) The average miRNA counts (shortlisted in A–C, $n = 116$) from severe SIRS and Sepsis groups was expressed as a ratio against no-SIRS controls (left and middle panels) or in between each others (right panel), resulting in fold differences (fd) for each blood miRNA (histograms). Green and red areas, respectively, represent miRNA decrease and increase, separated by $fd = 1$ (left dotted line) and $fd = +2$ (right dotted line). Compared to no-SIRS, many CIR-miRNAs had $fd > +2$ in SIRS (left), but not in sepsis ($fd < +2$, middle). When Sepsis/SIRS are compared CIR-miRNAs are mostly downregulated (right).

The libraries were finally eluted from gels, validated (for purity and correct insert size: 146 bp corresponding to ~22 nucleotides) on the High Sensitivity D1K ScreenTape (Agilent Technologies) and quantified by quantitative polymerase chain reaction (qPCR) prior to sequencing (Illumina HiSeq™ 2500). In each lane, $\sim 10^8$ NGS reads were acquired and, after filtering and sorting by library barcodes, sequences in any sample were mapped to miR-Base (release 20) database. The resulting mapped reads (called counts) were arbitrarily normalized as miRNA counts/ 10^5 . See Supplementary Material and Methods for further detail. Raw sequencing data is available at the repository ArrayExpress (Accession number: E-MTAB-4637).

Identification of miRNA normalizers in plasma. To identify miRNAs stably expressed in sepsis and SIRS relative to no-SIRS patients, for each average NGS miRNA count (technical duplicates, 5 groups

Figure 2. Shortlisting of internal normalizers in NGS and miRNA Q-PCR arrays. Plasma total RNA extracted and analyzed in NGS as described in Fig. 1, in 10 duplicate plasma pools (5 groups representative of 89 individuals) (A) or in 89 individuals samples using the miRCURY LNA Universal RT microRNA PCR technology (B). (A) Among the finally shortlisted miRNAs (miR-320a, miR-92b-3p and miR-486-5p), the fold-differences (fd) of average NGS counts seen in severe and non-severe sepsis and SIRS groups (8 pools representative of 73 individuals) relative to no-SIRS controls (2 duplicate pools, $n = 16$) are shown. (B) In miRNA qPCR arrays, normalizer miRNAs were tested for 89 individual patients in 5 groups: severe sepsis ($n = 21$); non-severe sepsis ($n = 8$); severe SIRS ($n = 23$); non-severe SIRS ($n = 21$); and patients without SIRS (no-SIRS controls, $n = 16$), in two independent technical repeat experiments. Because miR-92b-3p was below the level of detection in 22/89 patients, it was excluded from further analysis. The mean Cp of the miR-320a and miR-486-5p is shown in each group and was selected as an internal normalizer for the miRNA qPCR array dataset.

representative of 89 individuals) we calculated: (i) percentage residual counts relative to average counts across groups and (ii) fold-differences (fd) between sepsis and SIRS (severe and non-severe). Normalizer candidates had: percentage residual counts within $\pm 20\%$ when comparing any inflammatory disease group to no-SIRS and $fd = 1.00 \pm 0.20$ (i.e. not more than 20% differential NGS counts in severe/non-severe sepsis vs SIRS).

microRNA real-time qPCR array and cytokine analysis. Total plasma RNA was extracted from individual patients using the miRCURYTM RNA isolation-biofluids kit (Exiqon, Denmark). RNA was reverse transcribed (RT) and cDNA analyzed using the miRCURY LNATM Universal RT microRNA PCR, Polyadenylation and cDNA synthesis method (Exiqon, see Supplementary Material and Methods for details). Each microRNA was assayed by qPCR (microRNA Ready-to-Use PCR, Pick-&-Mix using ExiLent SYBR[®] Green master mix) in 2 independent technical repeats including negative controls (no-template from the RT reaction) using a LightCycler[®] 480 Real-Time PCR System (Roche). In each experimental group, ≥ 8 biological replicates were included. Assays returning 3 crossing point (Cp) values less than the negative control and $Cp < 37$ were accepted. The stability values of candidate normalizers were assessed using the 'NormFinder' software³⁷. Any qPCR data was normalized to the average Cp of internal normalizers detected in all samples (delta Cp, $dCp = \text{normalizer Cp} - \text{assay Cp}$). Cytokines were measured on Luminex LX200 as before²⁹ (see Supplementary Material and Methods).

Statistical analyses. Datasets were analyzed using the GraphPad Prism 6 and/or IBM SPSS Statistics 22 software. The D'Agostino and Pearson omnibus and/or Shapiro-Wilk tests were used to test normal data distribution. If not normally distributed, medians with interquartile ranges (IQR, rather than means and standard deviation, SD) are shown and Mann-Whitney U Test (rather than t-tests) were used to calculate p-values in 2-group comparisons. Significances across more than 2 groups were assessed by ANOVA (Kruskal-Wallis test). For the qPCR miRNA array dataset, a Benjamini-Hochberg p-value correction³⁸ was used to control for the number of false positives. The CIR-miRNA score (generated by binary logistic regression to predict SIRS vs sepsis) linearly combined the top performing 6 miRNA measurements in severe sepsis/SIRS patients. Multivariable analysis to correct for the effects of confounding variables was conducted using hierarchical multiple regression and hierarchical binary logistic regression (refer to Supplementary Materials and Methods for details). Correlations between CIR-miRNA scores and plasma levels of inflammatory mediators were evaluated using the Spearman rho and significances of the correlations. miRNA and cytokine analyses were conducted blind to the clinical data.

Results

Patients. Plasma samples used in the study came from 91 critically ill patients. Two samples with free hemoglobin (Hb) > 0.6 g/L were excluded as hemolytic from further analysis (Supplementary Fig. 1A), leaving 89 samples divided into five groups (Supplementary Fig. 1B): severe sepsis ($n = 21$); non-severe sepsis ($n = 8$); severe non-infective SIRS ($n = 23$); non-severe non-infective SIRS ($n = 21$); and patients without SIRS (no-SIRS controls, $n = 16$). Data describing demographics, clinical characteristics, sampling, severity of illness and key inflammatory biomarkers for study participants are shown in Table 1.

The median age of the patients was 66 years (IQR 54–75 years), 38 (43%) were male. Groups were well matched for age and gender ($p = 0.229$ and $p = 0.638$ respectively). By definition all 29 sepsis patients had an

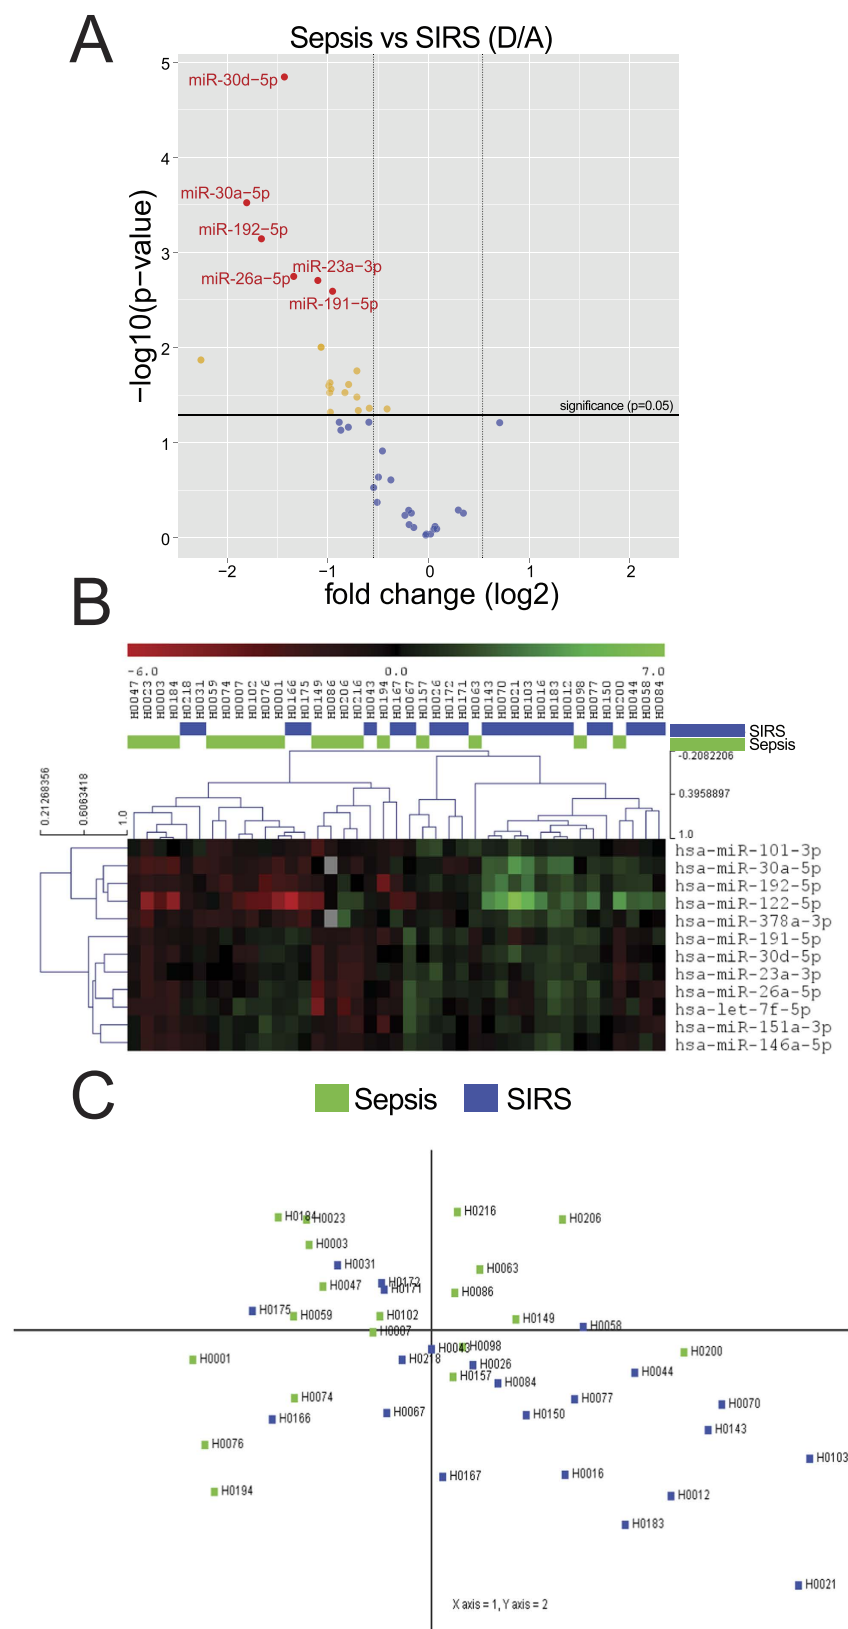

Figure 3. Shortlisted CIR-miRNAs measured with Exiqon miRNA qPCR arrays. In miRNA qPCR arrays, within each patient's specimen, Cp of a single miRNA is compared to the mean Cp of 2 normalizers (as from Fig. 2) to give delta-Cp (dCp). dCp of all patients are analyzed, comparing severe Sepsis (D, n = 21) and SIRS (A, n = 23). **(A)** Volcano plot shows fold changes (\log_2 , D/A) relative to p values ($-\log_{10}$) in each miRNA assay. In the upper left quadrant of the plot, around 20 miRNAs are significantly (red and yellow dots above the horizontal black line, which indicates a level of significance $p \leq 0.05$) downregulated in D/A ($\text{fd} < -1.5$, left vertical line), see Table 2. Orange and red dots represent significant differences by t-test ($p < 0.05$) with red

dots representing miRNA that also passed the Benjamini-Hochberg correction. No CIR-miRNA significantly increased in D/A. **(B)** Heatmap shows the top 12 significant miRNA clustering with opposite patterns in D/A. **(C)** Principal component analysis (PCA) transforms the top 5 significant miRNAs to maximize the visualization of differences across the severe sepsis and SIRS groups. The PCA plot shows that within the dataset it is possible to discriminate patients with SIRS (blue dots, mostly in the lower right quadrant of the PCA plot) away from patients with sepsis (Fig. 3C, green dots falling in other quadrants).

abdominal focus and all had surgical or radiological interventions. Non-sepsis patients were more heterogeneous with 39/60 (65%) being surgical (cancer surgery 17, abdominal surgery 16, cardiac surgery 4, and trauma 2), whilst the remainder were mixed medical patients. Patients with severe sepsis and severe non-infective SIRS had similar SOFA scores (Mean \pm SD: 8.19 ± 2.68 and 7.56 ± 2.31 respectively, $p = 1.00$) which were markedly higher than in patients with non-severe disease 1.13 ± 0.99 and 1.29 ± 0.96 ($p < 0.0001$ both for sepsis and non-infective SIRS). Patients with severe sepsis had markedly higher levels of C-reactive protein (CRP: 161.8 ng/ml; IQR 109.5–215.7 ng/ml) and procalcitonin (PCT: 8.8 ng/ml; IQR 2.15–39.2 ng/ml) than patients with severe SIRS (CRP: 5.50 ng/ml; IQR 1.90–18.2 ng/ml, $p < 0.0001$ and PCT: 0.20 ng/ml; IQR 0.10–1.10 ng/ml, $p = 0.0002$). PCT levels also tended to be lower among patients with mild rather than severe sepsis (1.40 ng/ml; IQR 0.32–8.82 ng/ml) but this was not statistically significant ($p = 1$).

Identification of plasma inflammation-related miRNAs by NGS. In order to identify which of the currently known 2588 human miRNAs are found in the blood of critically ill patients with and without SIRS, we used NGS to sequence and differentially quantitate miRNAs in plasma pools comprising all patients in five groups (Table 1). Plasma pools were preferred to individual samples because they decrease the impact of individual outliers on the analysis. To control for the bias of miRNAs from RBC in differential analysis, we compiled pools so that average levels of hemolysis were comparable (Supplementary Fig. 1B and Table 1). Total RNA was then extracted from equal volumes of plasma and technical duplicates of cDNA libraries for Illumina NGS created. Results from 10 pools representative of 89 individuals are shown in Fig. 1. On average, NGS reads/library were $7.94 \pm$ (SD) 1.36×10^6 and miRBase-mapped reads (counts) were $43.5 \pm$ (SD) 7.2%. Just below half of human microRNAs listed in miRBase.org (1097) returned counts in NGS (Fig. 1A) and were similarly distributed in each group. miRNAs present at low levels (< 1 read per 10^5 NGS counts across all five groups; Fig. 1A, orange area) showed high variability between the technical replicates and were excluded from further analysis. 244 miRNAs were expressed above $> 1/10^5$ counts (Fig. 1B) in at least one group and among these concordance between replicates was poor if average counts were $< 15/10^5$ (Fig. 1C, grey area) consistently across groups, leaving 116 miRNAs for subsequent analysis (Fig. 1D and Supplementary Table 1).

For each miRNA, fold differences (fd) were calculated comparing average counts in severe SIRS and sepsis with no-SIRS patients (Fig. 1D). Highly significant differences were seen when comparing plasma from patients with non-infective SIRS and patients with sepsis relative to no-SIRS controls, with the median fd for miRNAs being 2.64 (IQR: 2.10–3.29) and 1.52 (IQR: 1.15–1.92) respectively ($p < 0.0001$ and $n = 116$ for each comparison). We henceforth term the blood miRNAs that are affected in sepsis and non-infective SIRS, circulating inflammation-related miRNAs (CIR-miRNAs). In addition, when directly comparing sepsis and non-infective SIRS, CIR-miRNA levels were markedly lower in sepsis patients (median fd = 0.53; IQR: 0.45–0.74) (Fig. 1D, right panel).

Identification of normalizer miRNAs. To allow for robust comparison of miRNA levels in blood between individual samples we used NGS data to identify normalizer miRNAs present at consistent levels across the four inflammatory disease groups (Fig. 2A, $n = 73$) relative to the no-SIRS ($n = 16$) controls. This identified three candidate normalizers: miR-320a, miR-92b-3p and miR-486-5p that were expressed at stable levels across all inflammatory patient groups with levels varying by $< 20\%$ (Fig. 2A).

We validated these candidate NGS normalizers using qPCR miRNA arrays on individual patient samples ($n = 89$, Fig. 2B). While miR-92b-3p was below the level of detection in 22/89 patients, the optimal normalizer (by NormFinder stability value³⁷) was the average Cp of miR-320a and miR-486-5p. This performed better than any other single miRNA detected and was consistent across all 89 patients (Fig. 2B).

Identification of a set of miRNAs which discriminate severe sepsis from SIRS. We applied qRT-PCR to validate the NGS results and determine if the general decrease in CIR-miRNAs observed in sepsis compared with non-infective SIRS could be used to distinguish these states at an individual patient level.

To maximize the possibility to detect reliable candidates we selected CIR-miRNAs for high level of detection in blood (by excluding CIR-miRNAs with consistently less than $35/10^5$ NGS counts in any group) and with $fd \leq 0.66$ or $fd \geq 1.5$ (when comparing sepsis to SIRS), leaving a panel of 47 CIR-miRNAs (including normalizers) to be validated in 89 patient samples. For each patient sample, Cp of single miRNAs were compared to the mean Cp of internal normalizers, to give delta-Cp (dCp). In parallel, we scored hemolysis in qPCR miRNA arrays as miR-23a/miR-451a ratio and excluded one sample that scored $> 7^{39}$ from further analysis (Supplementary Fig. 2).

dCp were analyzed of patients with severe Sepsis ($n = 21$, group D in Fig. 3) and non-infective SIRS ($n = 23$, group A in Fig. 3). Confirming our NGS analysis (Fig. 3 and Table 2), the majority (~94%) of CIR-miRNAs had negative fold changes in qPCR analysis in the sepsis group compared with non-infective SIRS (Volcano plot in Fig. 3A). Table 2 lists 20 CIR-miRNAs that were statistically significantly decreased (t-test, $p < 0.05$) including the top 6 differentially expressed that passed the Benjamini-Hochberg correction³⁸ (respectively, the yellow and red dots above the horizontal black line, $p \leq 0.05$, and with $fd \leq -1.5$, left vertical line in Fig. 3A). No CIR-miRNAs were statistically significantly increased in severe sepsis compared to severe non-infective SIRS

Table 2. Significant differentially-expressed miRNAs in severe Sepsis (D) compared to SIRS (A).

(Fig. 3A). Furthermore, the top-12 significantly different CIR-miRNAs showed inverse patterns in sepsis and SIRS (heatmap in Fig. 3B).

To determine whether severe sepsis and non-infective SIRS are associated with distinct patterns of change in CIR-miRNAs we conducted a principal component analysis. A combination of top 5 significantly different CIR-miRNAs (miR-30d-5p, miR-30a-5p, miR-192-5p, miR-26a-5p and miR-23a-5p) was sufficient to achieve discrimination of severe sepsis from non-infective SIRS patients (Fig. 3C).

Relative to normalizers, dCp values in severe SIRS were significantly higher than in sepsis (Fig. 4A), indicating that CIR-miRNAs are more abundant in SIRS than in sepsis patients. When the data were plotted as receiver operator curves (ROC) each of the top 6 significantly different CIR-miRNAs (additionally including miRNA-191-5p) provided good to excellent discrimination with areas under the curve (AUC) between 0.742 to 0.861 (Fig. 4A). Hierarchical logistic regression (Supplementary Fig. 4A) confirmed that the predictive value of these 6 miRNAs is retained after controlling for SOFA score; age; sex; patient survival outcome and time of sample collection.

We further created a model combining levels of these 6 CIR-miRNAs into a score that maximized the distinction between non-infective SIRS and sepsis (Fig. 4B). In the model interpolation of the cohort, non-infective SIRS and sepsis patients tended to score respectively >0 and <0 ; hence the higher the model score the more likely patients are to have non-infective SIRS rather than sepsis, as described by a concomitant increase of multiple CIR-miRNAs (CIR-miRNA score). The ROC curves with AUC 0.917 (Fig. 4B, right) and AUC 0.89 (after multivariable correction analysis, as shown in Supplementary Fig. 4) for the model interpolation data show that the top-6 significant CIR-miRNAs combined together outperformed any single miRNA. Moreover, CIR-miRNAs either combined or used singularly mimicked and even outperformed the traditional sepsis biomarker, PCT (Supplementary Fig. 3).

Levels of CIR-miRNAs are inversely correlated with that of inflammatory cytokines. We obtained CIR-miRNA scores as a mathematical function of the plasma levels of 6 CIR-miRNAs found to be consistently reduced in sepsis (and preferentially leading to score <0). The CIR-miRNA scores were then correlated to plasma levels of pro-inflammatory mediators, and SOFA severity scores, across sepsis and SIRS patients (Fig. 5). CIR-miRNA scores did not correlate with SOFA scores (Fig. 5A). However, CIR-miRNA scores negatively correlated with levels of pro-inflammatory mediators, suggesting that a marked increase of multiple CIR-miRNAs is significantly associated with low levels of pro-inflammatory markers (CRP and PSP, Fig. 5B) and cytokines (IL-1, IL-8 and IL-6, Fig. 5C). Thus, in severe inflammatory disease, the levels of CIR-miRNAs change in the opposite direction to levels of pro-inflammatory mediators.

Discussion

We have undertaken a robust exploratory evaluation of circulating miRNAs among critically ill patients with sepsis and non-infective SIRS in comparison with internal control patients. We identified circulating inflammation-related miRNAs (CIR-miRNAs) that are broadly increased in both sepsis and non-infective SIRS patients when compared with no-SIRS controls. Among patients with severe sepsis, CIR-miRNA levels were lower than in patients with comparably severe *non-infective* SIRS. Furthermore, we have identified six CIR-miRNAs which were markedly reduced in sepsis compared with non-infective SIRS and performed well as discriminatory

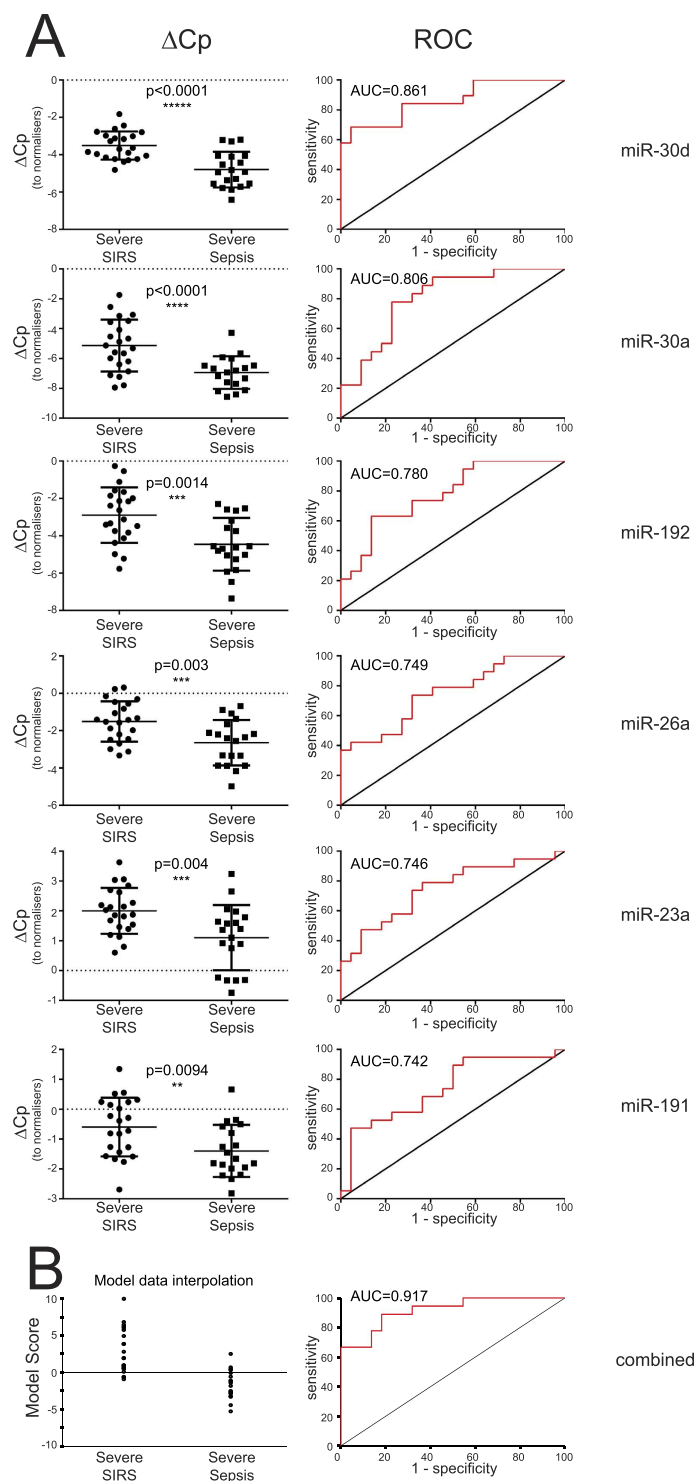

Figure 4. CIR-miRNAs are good-to-excellent biomarkers of sepsis. In miRNA qPCR arrays, data was analyzed as in Fig. 3 and the top-6 differentially expressed miRNA in sepsis compared to SIRS (after the Benjamini-Hochberg correction) are shown. **(A)** Left dot plots show ΔC_p values in severe SIRS vs sepsis in individual samples ($n = 21$ and $n = 23$ for sepsis and SIRS respectively, except $n = 20$ in sepsis for miRNA-30a-5p) together with the level of significance. The relative receiver operator curve (ROC, right) is shown with the Area Under the Curve (AUC). Each of the top 6 significant CIR-miRNAs is a good-to-excellent biomarker and CIR-miRNAs were mostly downregulated in Sepsis compared to SIRS in Exiqon miRNA qPCR arrays. **(B)** A model combines the top-6 significant CIR-miRNAs to maximize distinction between SIRS and sepsis. The CIR-miRNA score is directly related to the odds of having SIRS or sepsis given the measurements of the 6 top miRNAs (see Material and Methods for further details). Left dot plot shows the model interpolation of the experimental cohort: SIRS patients -that have high CIR-miRNA levels (in A)- tend to score >0 , whilst sepsis patients tend to score <0 . ROC (and AUC, right) shows that the 6 CIR-miRNAs combined outperformed single miRNAs.

Figure 5. Correlation of the model scores with pathology scores and plasma levels of immune mediators relevant in sepsis and SIRS. The model scores that combine the top-6 CIR-miRNA measurements in Severe SIRS and Severe Sepsis patients were plotted against (A) the pathology score (SOFA, sequential organ failure assessment); (B) current biomarkers of sepsis and inflammation, CRP (C-reactive protein) and PSP (pancreatic soluble protein); and (C) inflammatory cytokines, IL-6, IL-8, and IL-1. Correlation trends are shown with the linear regression model including Spearman rho and the significances of the correlations. Negative scores -typical of sepsis patients with lower plasma CIR-miRNAs (as in Fig. 4)- correspond to individuals with increased levels of inflammatory mediators. Positive scores -more often seen in SIRS patients and reflective of high plasma CIR-miRNAs- are found in individuals with low levels of inflammatory cytokines. Thus, CIR-miRNA levels negatively correlate with pro-inflammatory cytokines critical in systemic inflammatory conditions.

markers of these conditions. Combined together, these CIR-miRNAs were more discriminatory than traditional sepsis biomarkers such as PCT (Supplementary Fig. 3) and CRP²⁹. Notably, we found that CIR-miRNA levels correlate inversely with pro-inflammatory mediators.

Previous studies exploring the effect of sepsis and SIRS on circulating miRNAs have typically studied individual miRNAs shortlisted from mouse models or human cells²¹, stimulated with lipopolysaccharide (LPS)^{22–26}, made comparisons with healthy controls^{14,18,19} (rather than SIRS patients^{15,16,19,21}) or comparisons within sepsis patients for prognostic implications^{17,18,20}. Often, these studies had small patient cohorts (analyzed as individuals) and did not account for the nature of the underlying infection during sepsis and for severity of illness^{14–21}, both affecting the inflammatory response⁴⁰. Only in two previous studies^{14,17}, have circulating miRNAs been sought primarily with a genome-wide approach (with miRNA microarrays¹⁴ being less sensitive than NGS). Many previous studies^{14–21} have suffered from lack of rigorous normalization⁴¹ and bias coming from hemolysis (promoting the release miRNAs from RBCs^{31,32}).

Our study overcomes such limitations providing a definitive evaluation of CIR-miRNAs in human sepsis and SIRS. We propose a novel approach to the normalization of blood miRNAs. First, we excluded the bias of RBC-derived miRNAs from our analysis by balancing free Hb levels across the experimental groups and -unlike in any previous study^{14,17,41}- we normalized CIR-miRNAs against endogenous normalizing plasma miRNAs⁴² consistently expressed across all recruited individuals. The best normalizer for our dataset was a combination of miR-320a and miR-486-5p (while miR-92b-3p was excluded because its levels fell below the detection limit of qPCR in many individuals). Interestingly, miR-320a and miR-486-5p were included in the 5 best miRNAs for least concentration variations in plasma and/or serum in a recent detailed study of blood miRNAs (with n = 12 individuals) by an independent group⁹, suggesting that these miRNAs may be useful endogenous normalizers. Additionally, miR-486-5p is one of the most abundant miRNAs in RBC⁹ and its blood amounts may derive mostly by RBC³¹. Hence, it is not surprising that, after balancing haemolysis across the samples prior to miRNA analysis,

Figure 6. Proposed model for CIR-miRNA and inflammatory mediator plasma levels. The triangular shapes represent plasma levels of CIR-miRNA (circulating miRNA, top) and pro-inflammatory mediators (bottom). Based on our results, in Sepsis we found low levels of CIR-miRNAs correlating with increasing levels of pro-inflammatory mediators (dark red). In contrast, in SIRS patients CIR-miRNAs are more abundant than what is found for sepsis patients correlating with lower levels of pro-inflammatory markers (blue). We speculate that immunologically relevant CIR-miRNAs may exist that act as regulators of inflammatory processes especially during systemic inflammatory diseases. This hypothesis is consistent with recent data showing that regulatory cells secrete exosomes which exert miRNA-mediated immune-suppression.

we found relative stability of miR-486-5p in the individuals from our cohort. This supports that a two-stage normalization (Hb and endogenous miRNA) approach may enable the use of RBC-derived miRNAs as endogenous normalizers in future studies.

Interestingly none of the previously proposed “biomarkers of sepsis” was included in our best CIR-miRNAs that discriminate sepsis from SIRS, except for miR-23a (also found in¹⁴). We however confirmed modulation of miR-146a, miR-122, miR-223, and the Let-7 family- which collectively showed a tendency to decrease in sepsis compared to SIRS (Table 2). Hence, in contrast to previous reports we did not find increased levels of miR-223 and miR-146a^{14,17,18,43,44} associated with sepsis over SIRS. These differences likely result from the fact that previous studies compared sepsis patients directly to healthy individuals (rather than SIRS patients). In agreement, relative to control patients (no-SIRS), we also found that CIR-miRNAs are generally up-regulated in sepsis, thus reconciling our study with previous literature. Further our study is compatible with a previous report¹⁶ in which both miR-223 and miR-146a are reduced in sepsis compared to SIRS. Interestingly, 6/7 miRNAs investigated in the same study also showed a tendency to decrease in sepsis compared to SIRS. Other miRNAs previously proposed as “biomarkers of sepsis”, including miR-15a and miR-16¹⁹, miR-150^{14,21} (in agreement with¹⁵), and miR-4772-5p-iso²¹ were not confirmed in our independent cohort.

As we used the CRP to define our experimental groups, we cannot provide a direct comparison of the biomarker performance of CIR-miRNAs and CRP in this study. Nevertheless, within our own data the combination of the top 6 CIR-miRNAs outperformed the most discriminatory existing marker, PCT (Supplementary Fig. 3)²⁹ and exceeds previously published performance of CRP²⁹. The time of sample collection, sex, survival outcome, age and SOFA scores did not significantly affect the measurements of shortlisted CIR-miRNAs (Supplementary Fig. 4). Importantly, the predictive value of the top 6 CIR-miRNAs (either used alone or in combination) was generally well-preserved after controlling for a number of confounding variables in our cohort (Supplementary Fig. 4). However, our study observations remain limited to a single cohort of patients and as such constitute a “hypothesis generating” study. A larger prospective study will be needed to consolidate the proposed CIR-miRNAs as disease biomarkers in a different population. For instance, it should be noted that the small number of recruited patients with non-severe sepsis (n = 8) precluded the statistical analysis of the non-severe groups and future research will be needed to assess how CIR-miRNA levels are affected by disease severity. After matching for age, severity of the disease, time of sample collection, sex and free Hb, our study populations showed an intrinsic heterogeneity in the surgical to medical patient ratio (as 100% abdominal sepsis patients underwent surgery, decreased to average 65% in the control groups). Future studies should assess the impact of the focus of infection and surgery on levels of CIR-miRNAs.

It is presently unclear whether any of the top 6 CIR-miRNAs play a role in sepsis and SIRS. However, miR-191 and miR-26a have been recently associated with inflammatory and autoimmune conditions in humans and mice^{45–47}. Particularly, miR-26a was reported to limit inflammatory responses possibly by promoting regulatory T cell responses⁴⁶ or through NF-κB inhibition in chondrocytes⁴⁷. Also miR-23a has been implicated in inflammation via multiple pathways and it may: attenuate the cytotoxic activity in CD8 T cells⁴⁸; limit excessive T cell immunopathology by regulating reactive oxygen species⁴⁹; and/or regulate pro-inflammatory cytokine expression following TLR-signal in macrophages, via the NF-κB pathway⁵⁰. Kinases and transcription factors important in immune-cell differentiation and regulation such as Blimp-1⁵¹, p53/MDM2⁵² and PTEN⁵³ may be targets of miR-30a, miR-30d, miR-192 and miR26a, all CIR-miRNAs downregulated in sepsis, in our study. Further research in our laboratory is underway to evaluate whether and how these genes are relevant in sepsis.

We provide evidence that will support future studies defining the origin of CIR-miRNAs, whether they traffic in blood inside exosomes (vesicles) or in complexes with Argonaute^{8,54}, their targets and function. The magnitude of the changes we have observed in inflammation and the correlations with inflammatory cytokines suggest that CIR-miRNAs originate in cells of the immune system^{55,56}. We find that levels of CIR-miRNAs inversely correlate with levels of inflammatory cytokines that are typically elevated in sepsis such as IL-1 β , IL-6, and IL-8, and CRP^{3,57}. This opens up the possibility that CIR-miRNAs may be part of the anti-inflammatory response⁴ suppressing immune cell activation in severe sepsis and inflammation (Fig. 6). This hypothesis is compatible with the recent discovery that (murine) regulatory T cells suppress inflammatory responses by secreting a number of miRNAs analogous to the human CIR-miRNAs found in this study⁵⁶. How exactly the CIR-miRNAs fit into the inflammatory cascade in sepsis and SIRS remains to be determined in future studies. For example, miRNAs may be detected by Toll-like receptors as danger signals^{58,59} and transferred to antigen presenting cells⁶⁰, NK⁵⁹ and T⁵⁶ cells to drive cell-differentiation. Also, individual cellular miRNAs were shown to regulate inflammatory signaling cascades leading to immune cell activation or suppression (reviewed in^{61–63} and⁵⁰).

In summary, among critically ill patients, elevation of CIR-miRNAs is a hallmark of systemic inflammation. Quantitative and qualitative differences in CIR-miRNA levels exist in sepsis and non-infective SIRS. Our study provides proof-of-principle that sepsis and non-infective SIRS are associated with distinct changes in CIR-miRNAs which may be exploited for novel therapeutic and diagnostic approaches, whilst future investigations of the role of CIR-miRNAs in the immunopathogenesis of sepsis and non-infective SIRS are warranted.

Acknowledgements

We thank Mark Gregory, staff and patients who participated in the clinical study. We thank Dr. Maria Zabolotskaya and Dr. Chris Jones (University of Sussex) for technical help and discussions. We thank Dr. Watson and Dr. Talbot (ARK Genomics), and Dr. Sorrentino and Dr. Thorsten (Exiqon), for assistance. S.C. is supported by a Brighton and Sussex Medical School Internal Fellowship (University of Sussex). The funders had no role in study design, data collection and analysis, decision to publish or preparation of the manuscript.

Author Contributions

S.C., performed experiments and analyzed the data; S.C., S.F.N., F.K. and M.J.L. conceived and designed experiments; S.D., J.C. and M.J.L. conducted the clinical study; S.C., S.F.N., F.K. and M.J.L. wrote the first paper draft, all authors contributed to writing the final manuscript.

Additional Information

Supplementary information accompanies this paper at <http://www.nature.com/srep>

Competing financial interests: In relation to the work presented here, S.C., F.K., S.F.N. and M.J.L. declare to be inventors in a patent application submitted by the University of Sussex.
